

AMBA Bus Specification

Reference

AMBA™ Specification (Rev 2.0) by ARM - <http://www.arm.com>

Overview of the AMBA specification

The *Advanced Microcontroller Bus Architecture* (AMBA) specification defines an on-chip communications standard for designing high-performance embedded microcontrollers.

Three distinct buses are defined within the AMBA specification:

- the *Advanced High-performance Bus* (AHB)
- the *Advanced System Bus* (ASB)
- the *Advanced Peripheral Bus* (APB).

A test methodology is included with the AMBA specification which provides an infrastructure for modular macrocell test and diagnostic access.

Advanced High-performance Bus (AHB)

The AMBA AHB is for high-performance, high clock frequency system modules.

The AHB acts as the high-performance system *backbone* bus. AHB supports the efficient connection of processors, on-chip memories and off-chip external memory interfaces with low-power peripheral macrocell functions. AHB is also specified to ensure ease of use in an efficient design flow using synthesis and automated test techniques.

Advanced System Bus (ASB)

The AMBA ASB is for high-performance system modules.

AMBA ASB is an alternative system bus suitable for use where the high-performance features of AHB are not required. ASB also supports the efficient connection of processors, on-chip memories and off-chip external memory interfaces with low-power peripheral macrocell functions.

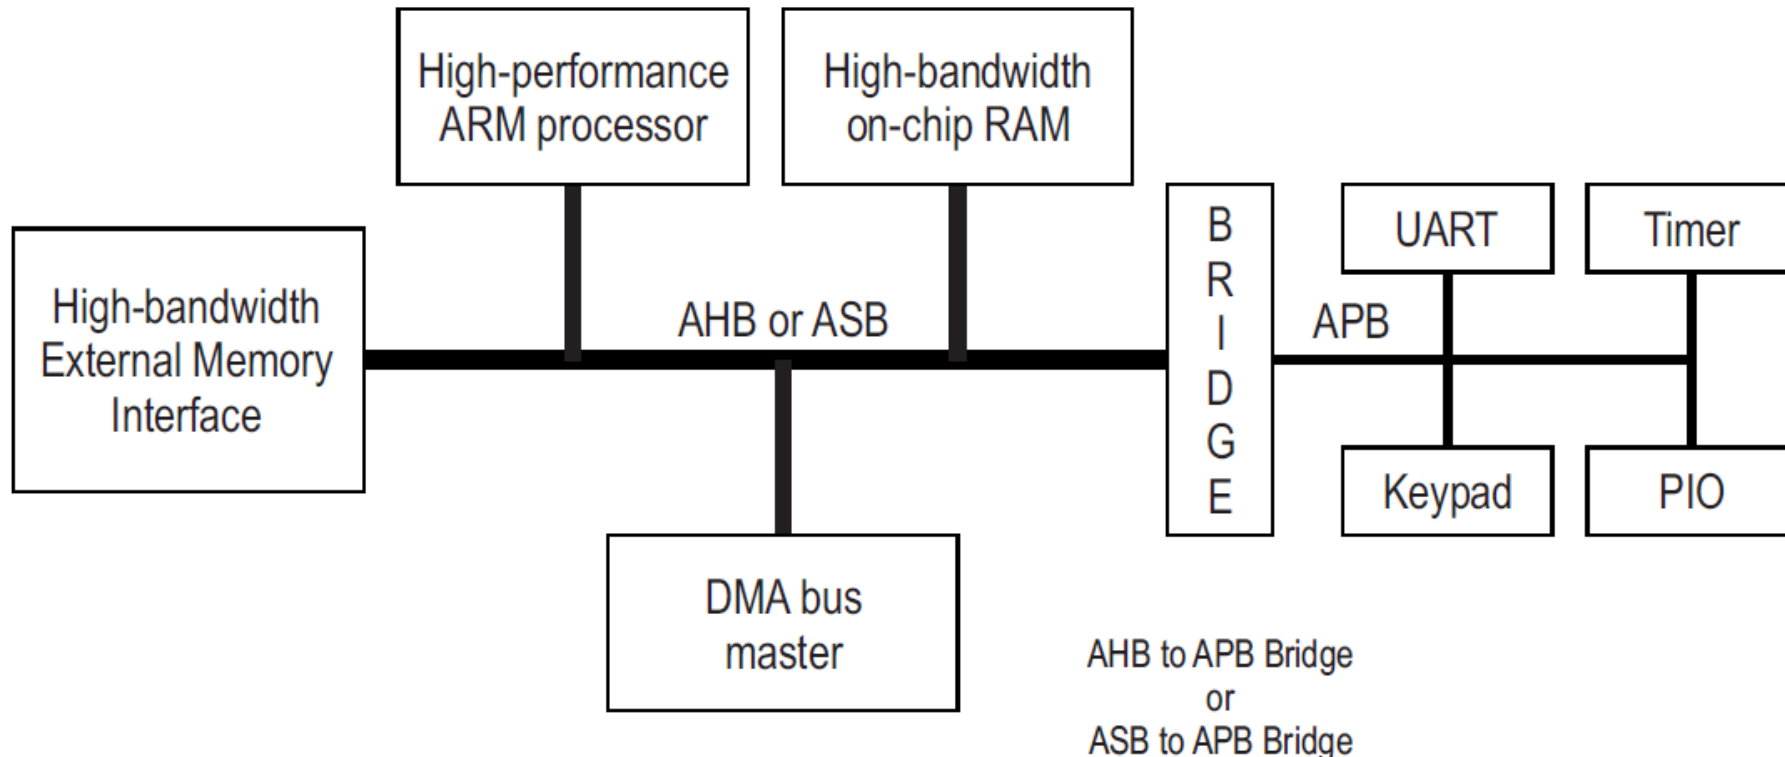

Advanced Peripheral Bus (APB)

The AMBA APB is for low-power peripherals.

AMBA APB is optimized for minimal power consumption and reduced interface complexity to support peripheral functions. APB can be used in conjunction with either version of the system bus.

A typical AMBA-based microcontroller

An AMBA-based microcontroller typically consists of a high-performance system *backbone* bus (AMBA AHB or AMBA ASB), able to sustain the external memory bandwidth, on which the CPU, on-chip memory and other *Direct Memory Access* (DMA) devices reside. This bus provides a high-bandwidth interface between the elements that are involved in the majority of transfers. Also located on the high-performance bus is a bridge to the lower bandwidth APB, where most of the peripheral devices in the system are located (see Figure 1-1).

Introducing the AMBA AHB

AHB is a new generation of AMBA bus which is intended to address the requirements of high-performance synthesizable designs. It is a high-performance system bus that supports multiple bus masters and provides high-bandwidth operation.

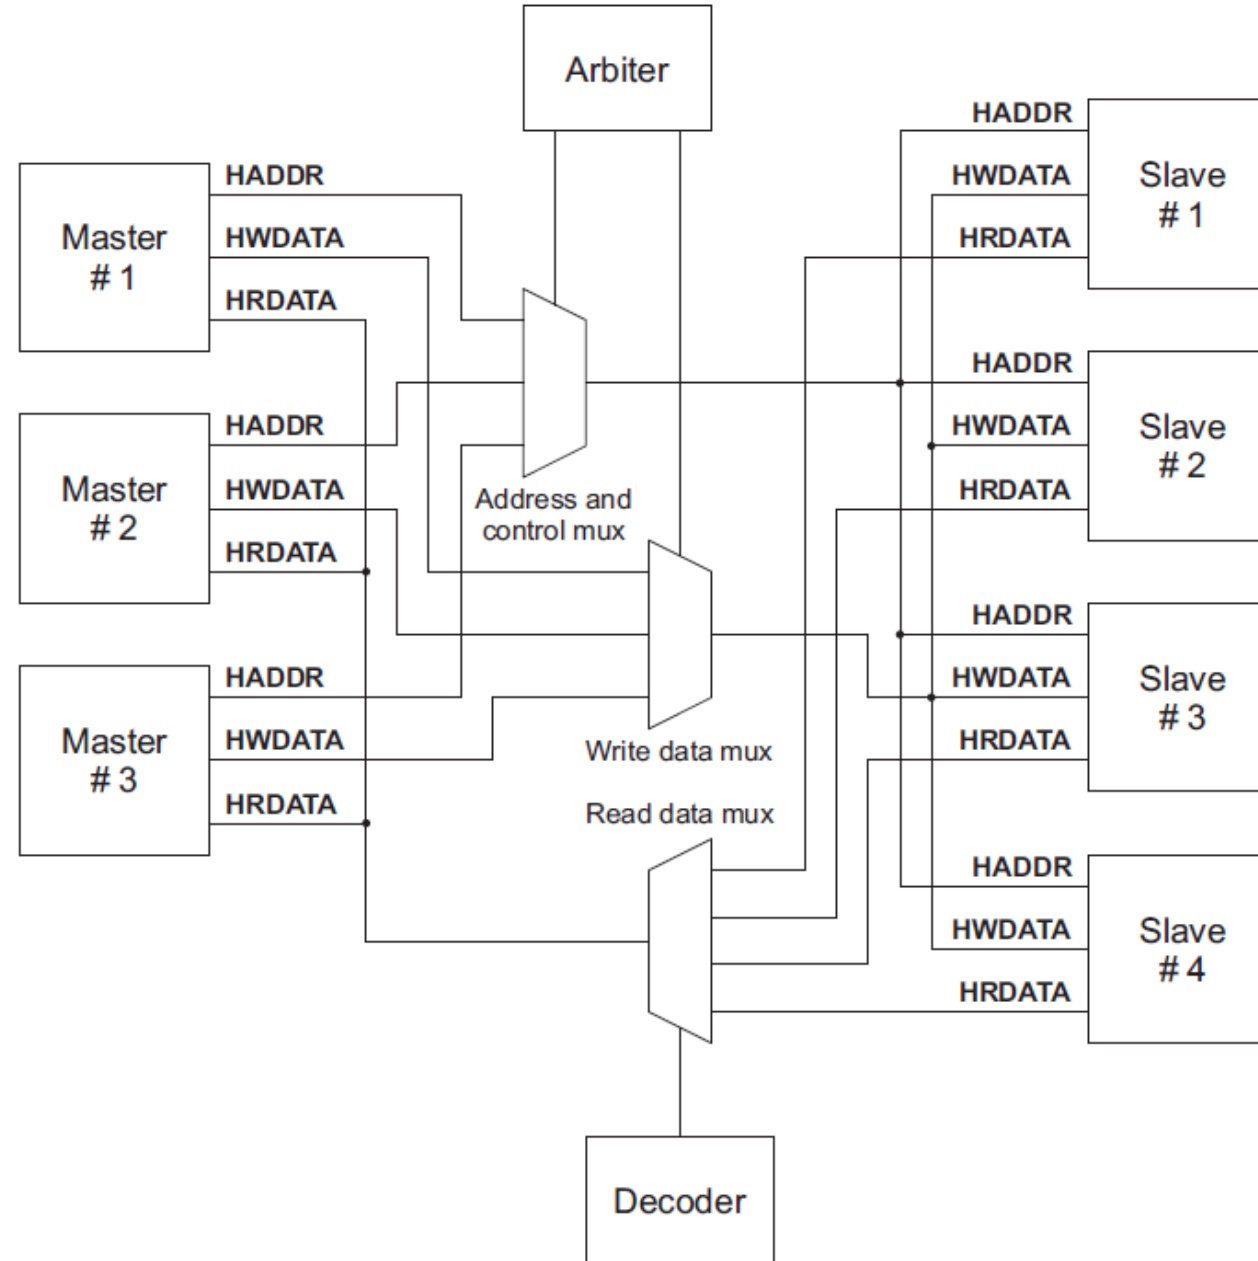

AMBA AHB implements the features required for high-performance, high clock frequency systems including:

- burst transfers
- split transactions
- single-cycle bus master handover
- single-clock edge operation
- non-tristate implementation
- wider data bus configurations (64/128 bits).

A typical AMBA AHB system design contains the following components:

AHB master	A bus master is able to initiate read and write operations by providing an address and control information. Only one bus master is allowed to actively use the bus at any one time.
AHB slave	A bus slave responds to a read or write operation within a given address-space range. The bus slave signals back to the active master the success, failure or waiting of the data transfer.
AHB arbiter	<p>The bus arbiter ensures that only one bus master at a time is allowed to initiate data transfers. Even though the arbitration protocol is fixed, any arbitration algorithm, such as <i>highest priority</i> or <i>fair</i> access can be implemented depending on the application requirements.</p> <p>An AHB would include only one arbiter, although this would be trivial in single bus master systems.</p>
AHB decoder	<p>The AHB decoder is used to decode the address of each transfer and provide a select signal for the slave that is involved in the transfer.</p> <p>A single centralized decoder is required in all AHB implementations.</p>

Bus interconnection

AMBA AHB operation

Before an AMBA AHB transfer can commence the bus master must be granted access to the bus. This process is started by the master asserting a request signal to the arbiter. Then the arbiter indicates when the master will be granted use of the bus.

A granted bus master starts an AMBA AHB transfer by driving the address and control signals. These signals provide information on the address, direction and width of the transfer, as well as an indication if the transfer forms part of a burst. Two different forms of burst transfers are allowed:

- incrementing bursts, which do not wrap at address boundaries
- wrapping bursts, which wrap at particular address boundaries.

A write data bus is used to move data from the master to a slave, while a read data bus is used to move data from a slave to the master.

Every transfer consists of:

- an address and control cycle
- one or more cycles for the data.

The address cannot be extended and therefore all slaves must sample the address during this time. The data, however, can be extended using the **HREADY** signal. When LOW this signal causes wait states to be inserted into the transfer and allows extra time for the slave to provide or sample data.

AMBA AHB operation

During a transfer the slave shows the status using the response signals, **HRESP[1:0]**:

OKAY	The OKAY response is used to indicate that the transfer is progressing normally and when HREADY goes HIGH this shows the transfer has completed successfully.
ERROR	The ERROR response indicates that a transfer error has occurred and the transfer has been unsuccessful.
RETRY and SPLIT	Both the RETRY and SPLIT transfer responses indicate that the transfer cannot complete immediately, but the bus master should continue to attempt the transfer.

AMBA AHB operation

Basic transfer

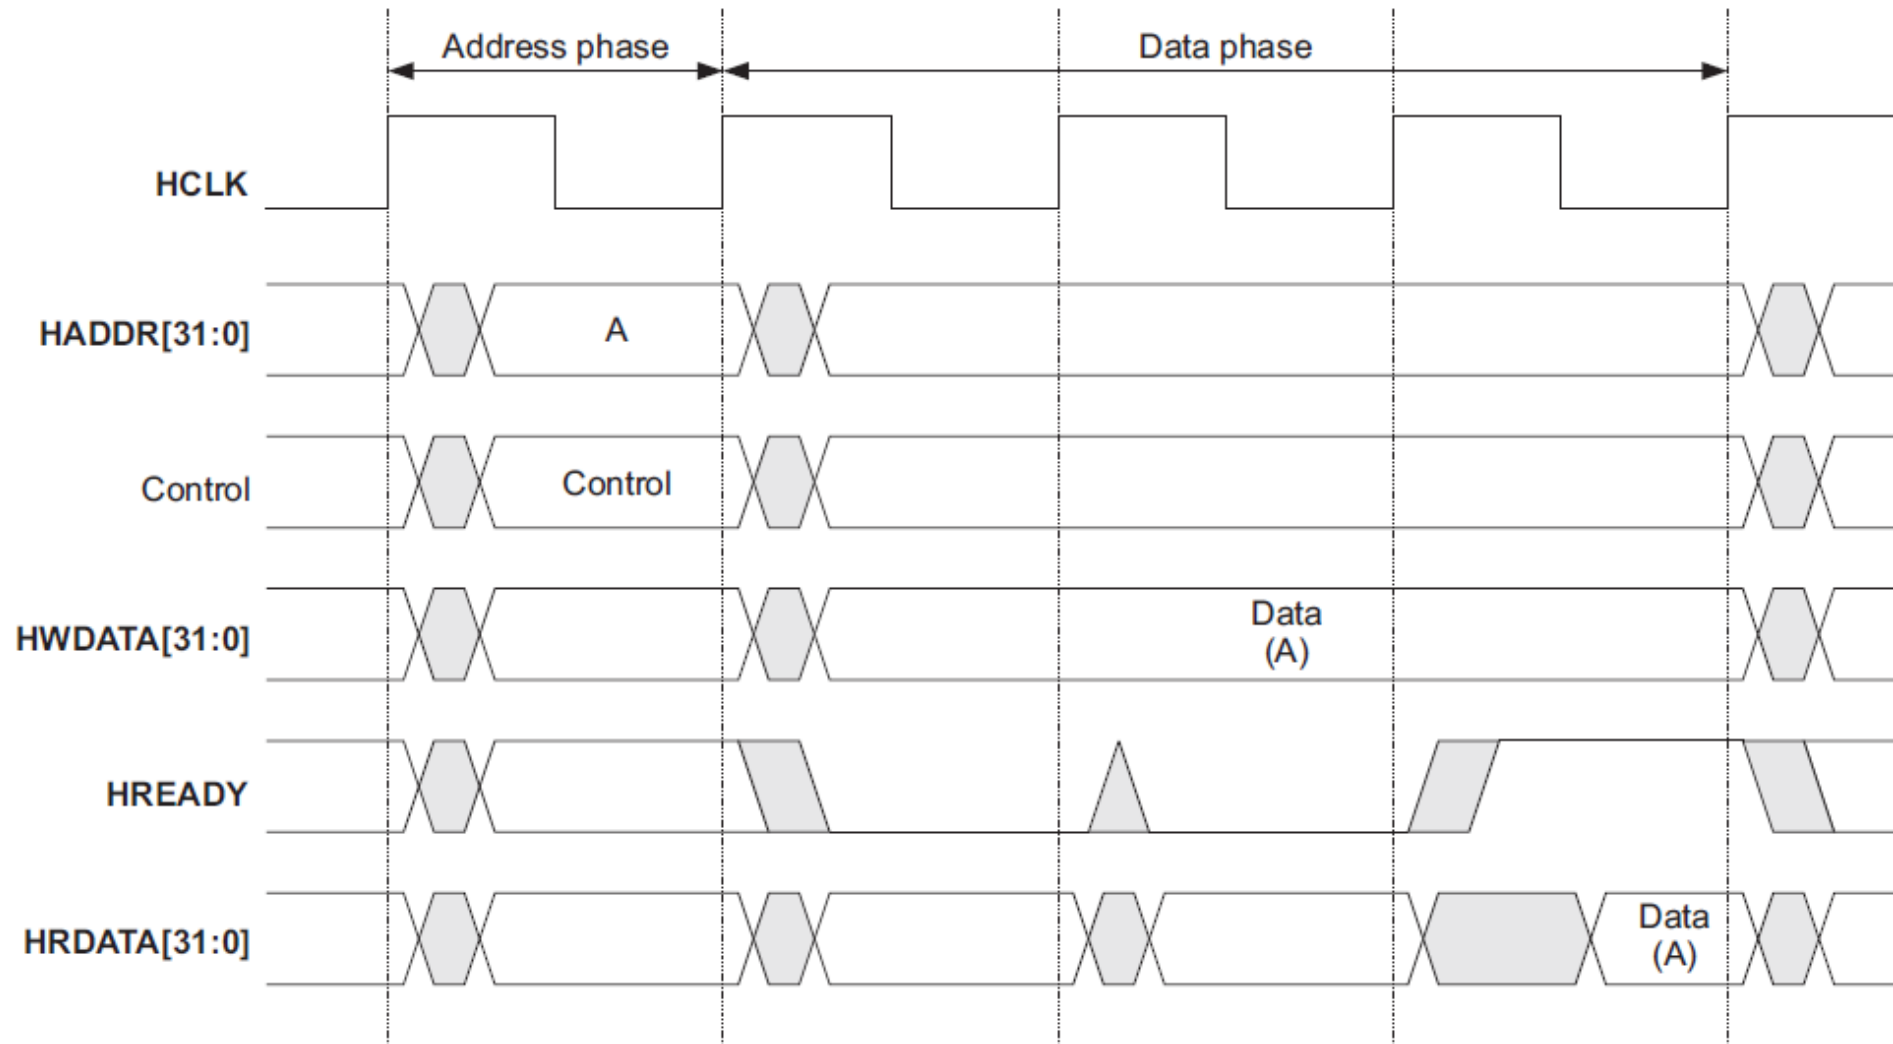

- **HREADY** - HIGH indicates that a transfer has finished on the bus.

Transfer type

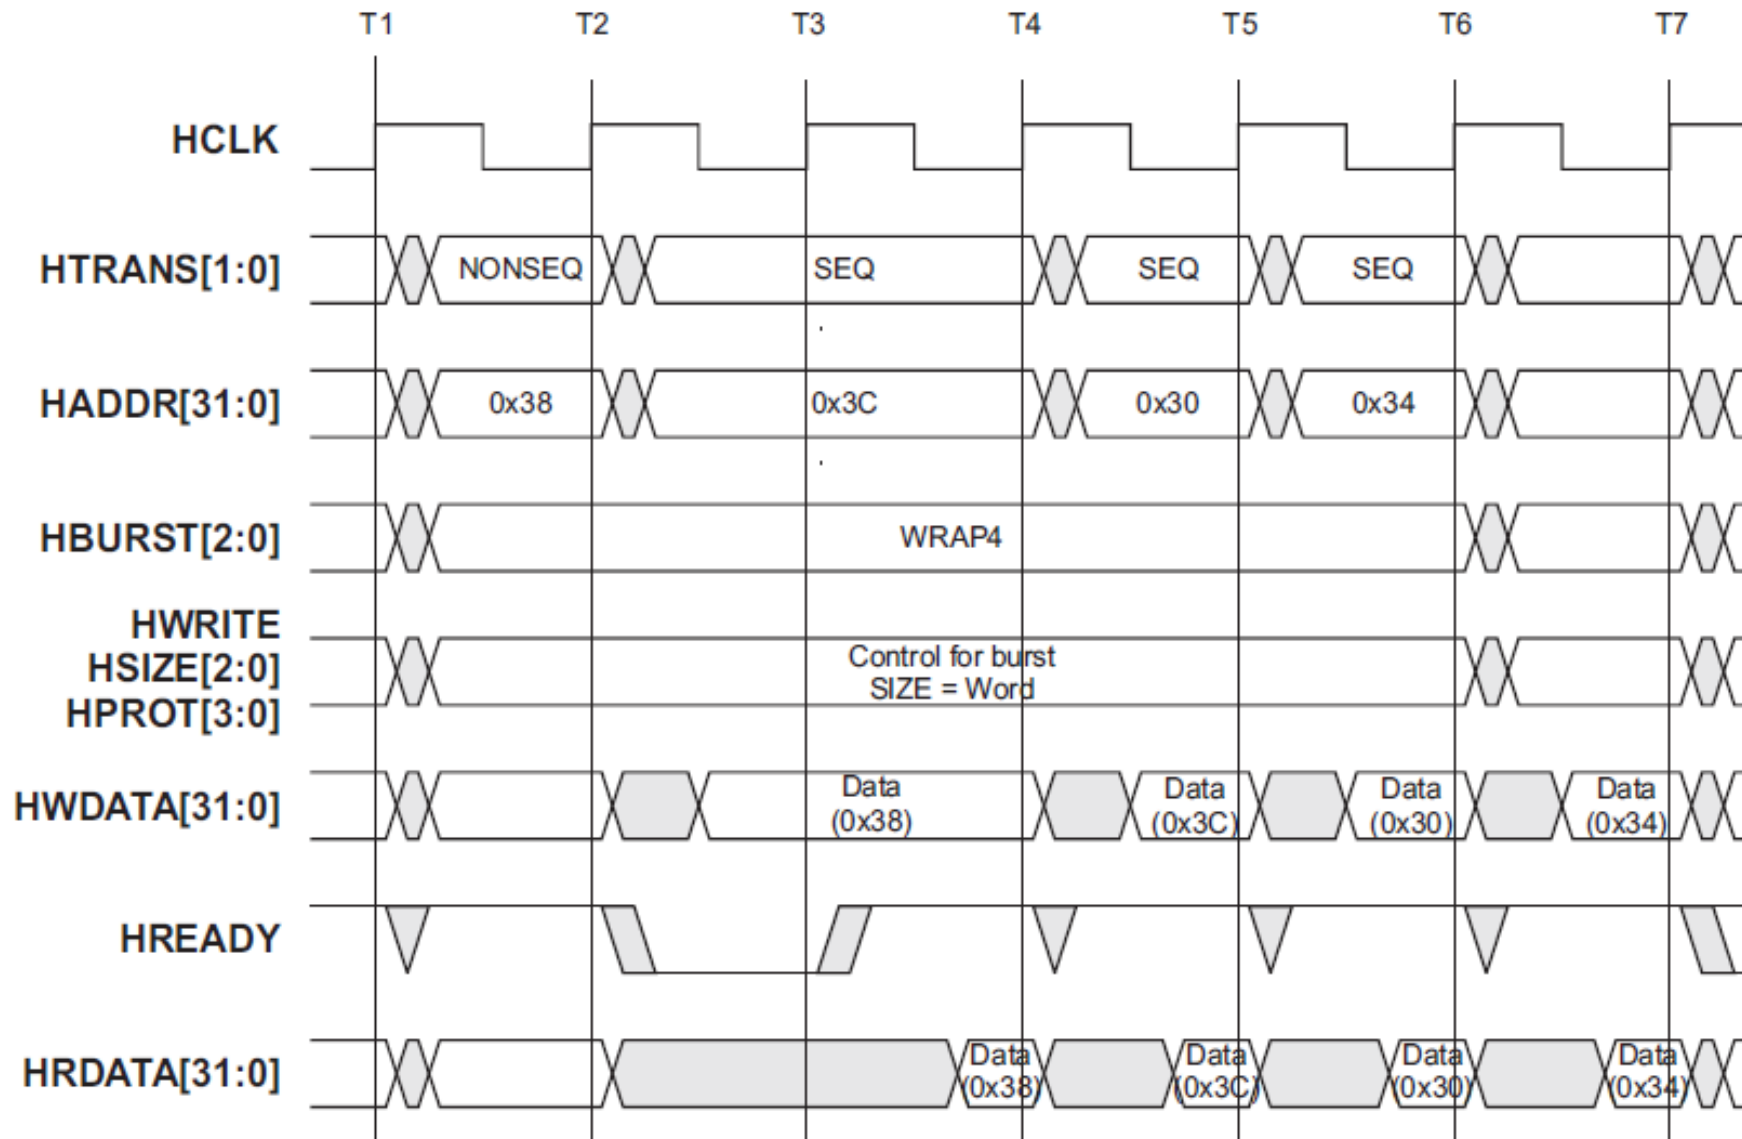

Transfer type examples

- **NONSEQ** - indicates the first transfer of a burst or a single transfer. The address and control signals are unrelated to the previous transfer
- **SEQ** - the remaining transfers in a burst are **SEQUENTIAL** and the address is related to the previous transfer. The control information is identical to the previous transfer.
- **IDLE**- indicates that no data transfer is required
- **BUSY** The **BUSY** transfer type allows bus masters to insert **IDLE** cycles in the middle of bursts of transfers. This transfer type indicates that the bus master is continuing with a burst of transfers, but the next transfer cannot take place immediately.

AMBA AHB operation

Burst operation

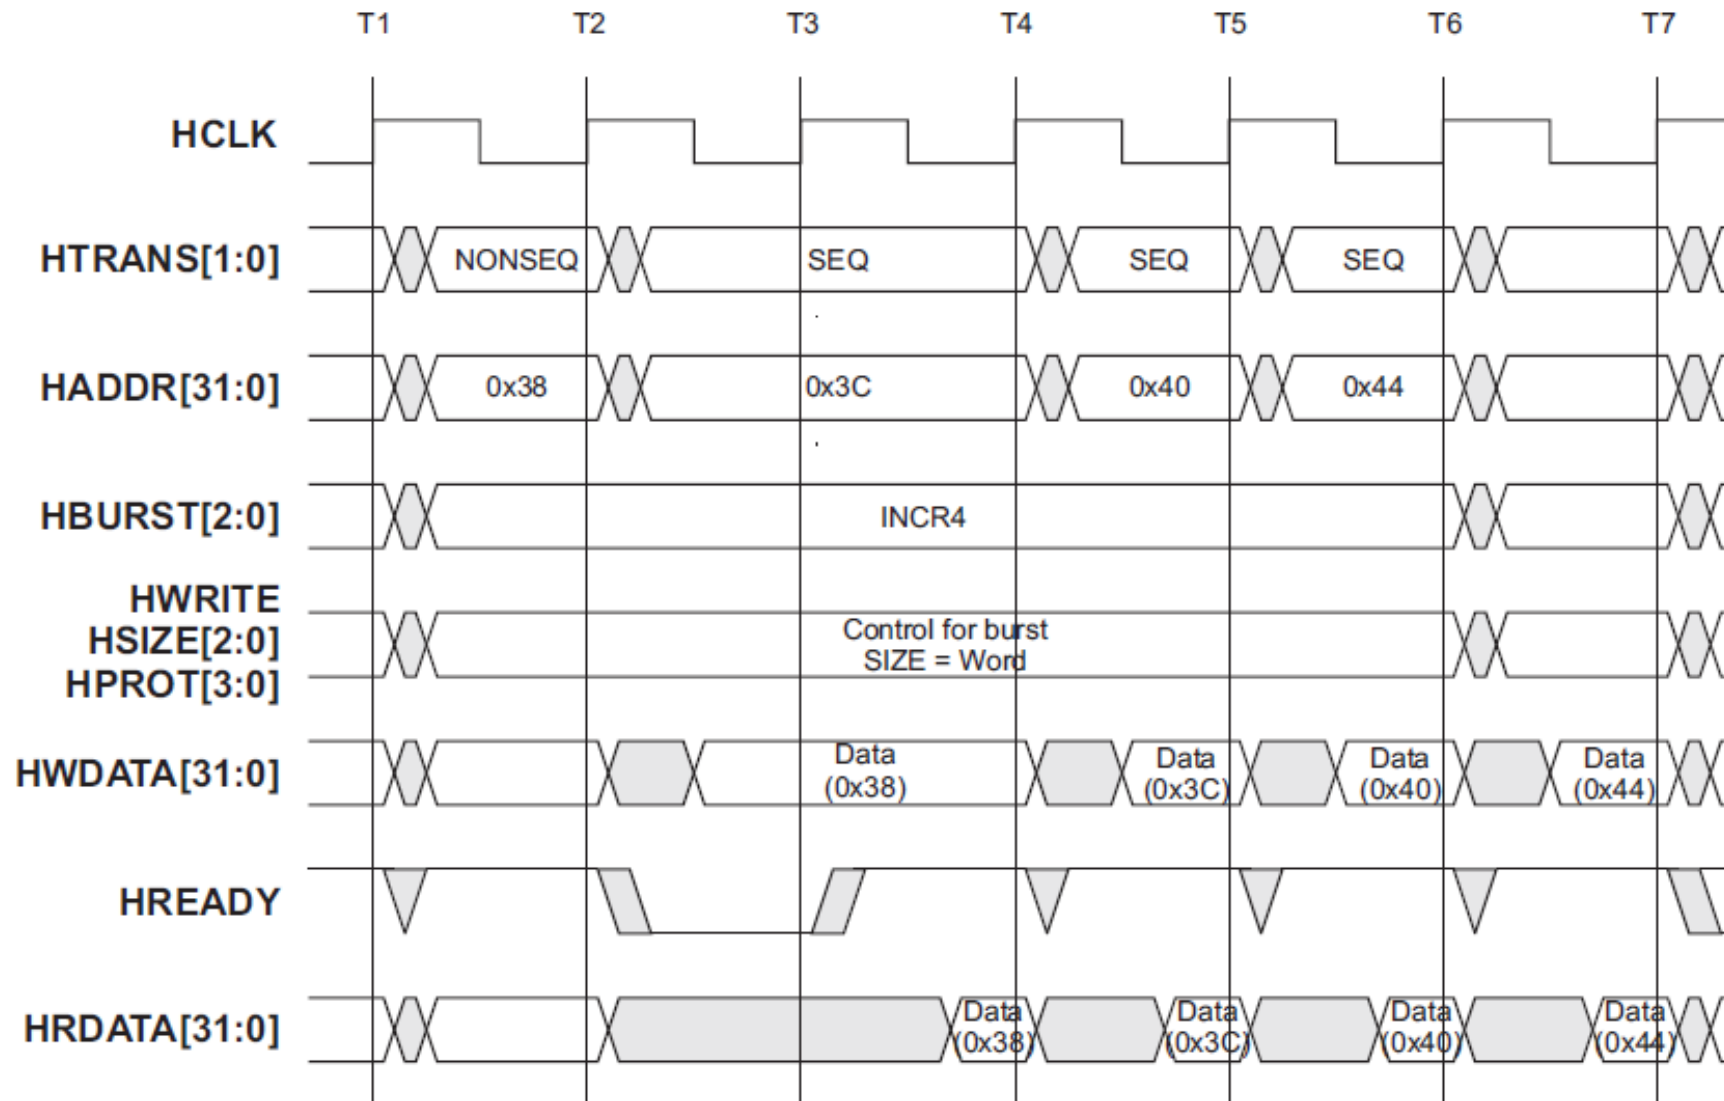

Four-beat wrapping burst

- Address of the transfers in the burst will wrap when the boundary is reached.
- A four-beat wrapping burst of word (4-byte) accesses will wrap at 16-byte boundaries.

AMBA AHB operation

Burst operation

- Bursts must not cross a 1kB address boundary.

Four-beat incrementing burst

Introducing the **AMBA APB**

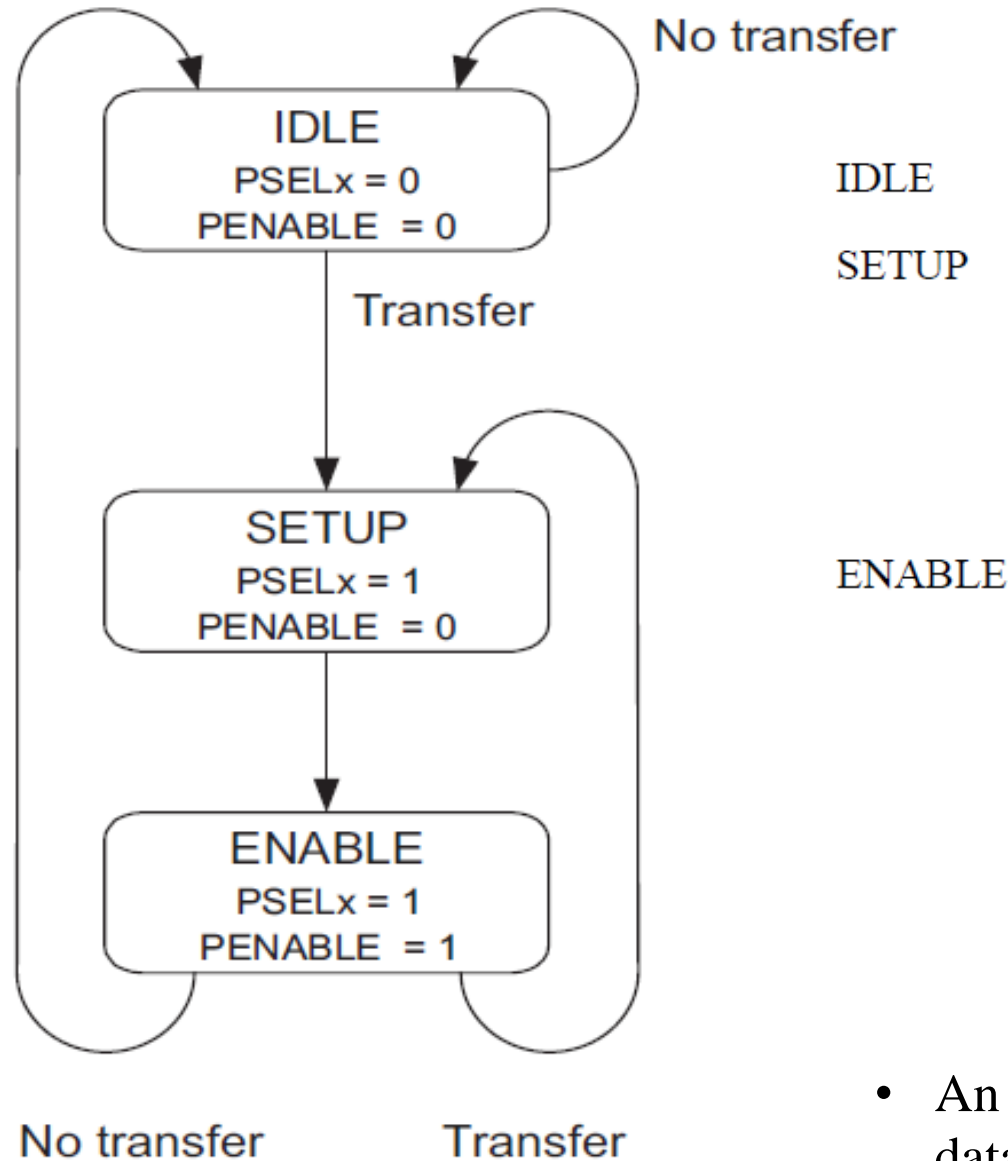

The APB is part of the AMBA hierarchy of buses

The APB bridge appears as a slave module which handles the bus handshake and control signal retiming on behalf of the local peripheral bus.

An AMBA APB implementation typically contains a single APB bridge which is required to convert AHB or ASB transfers into a suitable format for the slave devices on the APB. The bridge provides latching of all address, data and control signals, as well as providing a second level of decoding to generate slave select signals for the APB peripherals.

AMBA APB

State diagram

IDLE The default state for the peripheral bus.

SETUP When a transfer is required the bus moves into the SETUP state, where the appropriate select signal, **PSELx**, is asserted. The bus only remains in the SETUP state for one clock cycle and will always move to the ENABLE state on the next rising edge of the clock.

ENABLE In the ENABLE state the enable signal, **PENABLE** is asserted. The address, write and select signals all remain stable during the transition from the SETUP to ENABLE state.

The ENABLE state also only lasts for a single clock cycle and after this state the bus will return to the IDLE state if no further transfers are required. Alternatively, if another transfer is to follow then the bus will move directly to the SETUP state.

It is acceptable for the address, write and select signals to glitch during a transition from the ENABLE to SETUP states.

- An AMBA APB bus transfer is a read or write operation of a data object, which always requires two bus cycles
